

HEART FAILURE

This information sheet is for your general information and is not a substitute for medical advice. You should contact your doctor or other healthcare provider with any questions about your health, treatment or care.

What is heart failure?

The heart works as a pump that is responsible for distributing blood throughout the body, supplying oxygen and nutrients to all the organs. Heart failure is a condition that occurs when the heart muscles work less effectively than normal and cannot pump blood as well as they would usually do.

As a result of heart failure, the heart may become enlarged or thickened and may also weaken gradually. The heart will continue pumping, but with less efficiency.

Causes of heart failure

Conditions that damage the heart muscle result in heart failure. The common conditions include:

- coronary artery (heart) disease
- hypertension (high blood pressure)
- myocardial infarction (previous heart attack)
- cardiomyopathy
- diabetes
- valvular heart disease.

Symptoms of heart failure

- Shortness of breath is the most common symptom. It may occur while doing strenuous physical activities or walking a long distance; or while performing daily, routine activities such as cleaning. You may wake up from your sleep feeling short of breath. In this instance, it may be useful to sleep with additional pillows. Always report the level of shortness of breath to your doctor during your consultations.
- Ankle swelling. Fluid has accumulated in the ankles due to gravity.
- Weight gain. If your weight increases by 1.5kg over the duration of a day, it means that the heart failure could be worsening. You should restrict your fluid intake and contact your doctor.
- Fatigue.
- Rapid heartbeat (even while resting), dizziness and light-headedness.
- Loss of appetite.

What tests are done?

Chest x-ray

The test is used to detect fluid on the lung, which is an important sign of heart failure.

Electrocardiogram (ECG)

This test records the electrical activity of the heart and assists in determining a cause of the heart failure.

Echocardiogram

This test records a picture of the heart chambers, as generated via ultrasonic waves. It can record the degree of the heart failure and assist in determining a cause for the heart failure.

Blood tests

Various blood tests will be requested by your doctor that will assist in determining a cause for the heart failure and monitor for the consequences of the heart failure on your other organs.

Living with heart failure

Lifestyle modifications and medication are the two important components for the successful management of heart failure. Both are important to help you live life to the fullest, avoid serious illness and remain out of hospital.

Lifestyle modifications

- *Restrict your salt intake.* Salt causes your body to retain fluid and aggravates the heart failure. It is therefore important to reduce your salt intake and not to add any salt to your food. It would be beneficial if you regularly check the nutritional labels on food packages and choose products that contain less than 120mg of sodium per 100g serving. Avoid salty seasonings, processed foods and take-away foods that are notorious for their high salt content. Use garlic, herbs and spices instead of salt.
- It is very important to *monitor your weight* regularly.
- Your doctor may request that you *limit your fluid intake*. This could be in the range of 1 to 1.5 litres per day. Weight gain often means that fluid is accumulating in the body (1kg = roughly 1 litre of body fluid). It may therefore become necessary to measure your weight daily, preferably at the same time each day. Reduce fluid intake if your weight increases.
- *Limit your alcohol intake* as alcohol can damage your heart. Your doctor may ask you to reduce your alcohol to about two standard drinks per day or none at all.
- *Quit smoking.* Smoking damages your arteries, including those supplying blood to the heart. To quit smoking is an important part of the management of heart disease and it has been shown to greatly improve symptoms.
- *Physical activity.* Regular, moderate exercise is beneficial and is encouraged. These exercises may include brisk walking, cycling and stretching. Try to exercise at least four days per week for at least 30 minutes at a time.

Medication

- Diuretics are prescribed to reduce the excess fluid in your body.
- Discuss with your doctor whether you should take an extra water pill if your weight increases more than 1.5 kg from day to day.
- ACE inhibitors reduce the workload of the heart, block the effects of detrimental hormones and dilate blood vessels.
- There are many other different types of medication used for heart failure. If you feel that your medication is not working or is causing side effects, please alert your doctor.
 - Your pharmacist will also be able to tell you more about your medication.
 - Never stop taking your medication without first discussing it with your doctor.
 - Always ensure that you have enough medication with you.

Various alternative treatment options are available to manage any complications if you have not adequately responded to lifestyle modification or your medication. These include devices to control your heart rhythm, such as pacemakers or implantable defibrillators. Another option would be a heart transplant. However, careful screening needs to be done as not all people with heart failure are suitable candidates for a heart transplant.

Complications of heart failure

- Enlarging of the heart
- Abnormal heart rhythms
- Heart attack
- Stroke

It is information to keep the following information handy when seeing your doctor or when dealing with your medical scheme's chronic disease management programme:

- Any emergency room visits
- Hospital admissions
- Your weight
- Shortness of breath (at rest, during routine activity and with excessive activity)
- Any medication you're taking
